

Nonlinear oscillation of a dielectric elastomer balloon

Jian Zhu, Shengqiang Cai and Zhigang Suo*

Abstract

Much of the existing literature on dielectric elastomers has focused on quasi-static deformation. However, in some potential applications, the elastomer deforms at high frequencies and undergoes nonlinear oscillation. While nonlinear oscillation has been studied in many areas of science and engineering, we are unaware of any theoretical analysis of nonlinear oscillation of dielectric elastomers. This paper reports a theoretical study of the dynamic behavior of a dielectric elastomer balloon subject to a combination of pressure and voltage. When the pressure and voltage are static, the balloon may reach a state of equilibrium. We determine the stability of the state of equilibrium, and calculate the natural frequency of the small-amplitude oscillation around the state of equilibrium. We focus on the parametric responses of the dielectric elastomer balloon. When the voltage is sinusoidal, the balloon resonates at multiple frequencies of excitation, giving rise to superharmonic, harmonic and subharmonic responses. When the frequency of excitation varies continuously, the oscillating amplitude of the balloon may jump, exhibiting hysteresis.

INTRODUCTION

Subject to a voltage through its thickness, a thin membrane of a dielectric elastomer reduces in thickness and expands in area. The strain of the membrane induced by the voltage can be large, readily exceeding 100%. This and related phenomena are being developed for applications in electromechanical transducers.^{1–7} Much of the existing literature on dielectric elastomers has focused on quasi-static deformation, where the effect of inertia is negligible. In some potential applications, however, elastomers deform at high frequencies, up to 50 kHz, and function as vibration sources,⁸ high-speed pumps^{9–12} and acoustic equipment.^{13,14}

In a large-strain, high-frequency application, the elastomer may undergo nonlinear oscillation. While nonlinear oscillation has been studied in many areas of science and engineering,^{15,16} we are unaware of any theoretical analysis of nonlinear oscillation of dielectric elastomers. To explore the subject, this paper reports a study of an idealized system: a dielectric elastomer balloon of a spherical shape, subject to a combination of pressure and voltage. Dielectric elastomer balloons have been studied as pumps¹² and loudspeakers,¹³ as well as elements of shell-like actuators.^{17,18}

The plan of this paper is as follows. The following section derives the equation of motion using the method of virtual work. The section after that describes the state of equilibrium when the pressure and voltage are static. We then discuss the small-amplitude oscillation around the state of equilibrium, and the stability of the state of equilibrium against small perturbation. The section after that studies parametric excitation, where the pressure is static but the voltage is sinusoidal. Finally, we show that, when the frequency of excitation is varied continuously, the oscillating amplitude of the balloon can jump, exhibiting hysteresis.

EQUATION OF MOTION

Figure 1 shows a spherical balloon of radius R and thickness H in the undeformed state. The membrane of the balloon is a dielectric elastomer, taken to be incompressible, of density ρ . The membrane is coated on both faces with compliant electrodes. We will neglect any stress in the electrodes, but may add the mass of the electrodes to that of the membrane.

When the pressure inside the balloon exceeds the pressure outside by p and the two electrodes are subject to a voltage Φ , the balloon deforms to radius r and the two electrodes gain charges $+Q$ and $-Q$. Let λ be the stretch of the membrane, namely

$$\lambda = \frac{r}{R} \quad (1)$$

Let D be the electric displacement in the membrane, namely

$$D = \frac{Q}{4\pi r^2} \quad (2)$$

The balloon is taken to deform under an isothermal condition, and the fixed temperature will not be considered explicitly. Consequently, the balloon is a thermodynamic system of two independent variables, λ and D . We next formulate a model to evolve this system in time t .

The thermodynamics of the dielectric elastomer is characterized by the density of the Helmholtz free energy as a function of the

Figure 1. Dielectric elastomer balloon deforms under a pressure and a voltage.

two independent variables, $W(\lambda, D)$. We will adopt the model of an ideal dielectric elastomer.¹⁹ The model assumes that the elastomer is a network of long and flexible polymers with a low density of crosslinks, so that the crosslinks almost do not constrain the process of polarization. Once the effect of crosslinks on polarization is neglected, the dielectric behavior of the elastomer is liquid-like, unaffected by deformation. Consequently, the free-energy function of the dielectric elastomer is written as a sum of two parts:

$$W(\lambda, D) = \frac{\mu}{2}(2\lambda^2 + \lambda^{-4} - 3) + \frac{D^2}{2\varepsilon} \quad (3)$$

The first part is the elastic energy, where μ is the shear modulus. For simplicity, we use the neo-Hookean model to describe the elasticity of the network; other models of elasticity may be used. The second part in Eqn (3) is the dielectric energy, where ε is the permittivity. For an ideal dielectric elastomer, the permittivity is taken to be a constant independent of deformation.

The model of ideal dielectric elastomers has been used almost exclusively in the literature to analyze devices. However, recent experiments on VHB (an acrylic-based elastomer made by 3M), the most studied dielectric elastomer, have shown that the permittivity may vary by a factor of two when the elastomer undergoes large deformation.¹⁸ See Zhao and Suo²⁰ for a review of thermodynamic models for dielectric elastomers. While the general considerations in this paper are valid for arbitrary function $W(\lambda, D)$, we will use the function (3) in numerical calculations.

When the charge on the electrodes varies by δQ , the applied voltage does work $\Phi \delta Q$. When the radius of the balloon varies by δr , the pressure does work $4\pi r^2 p \delta r$, and the inertial force does work $-4\pi R^2 H \rho (d^2 r / dt^2) \delta r$. We neglect any viscous force. Thermodynamics dictates that, for arbitrary variation of the system, the variation of the free energy of the membrane should equal the work done by the voltage, the pressure and the inertia, namely

$$4\pi R^2 H \delta W = \Phi \delta Q + 4\pi r^2 p \delta r - 4\pi R^2 H \rho \frac{d^2 r}{dt^2} \delta r \quad (4)$$

Inserting Eqns (1) and (2) into Eqn (4), and recalling that the balloon is a system of two independent variables, λ and D , we obtain that

$$\frac{\partial W(\lambda, D)}{\partial \lambda} = \frac{2\Phi D \lambda}{H} + \frac{pR}{H} \lambda^2 - R^2 \rho \frac{d^2 \lambda}{dt^2} \quad (5)$$

$$\frac{\partial W(\lambda, D)}{\partial D} = \frac{\Phi}{H} \lambda^2 \quad (6)$$

Equation (5) balances momentum and Eqn (6) enforces electrostatic equilibrium. For an ideal dielectric elastomer, Eqn (6) recovers

Figure 2. Subject to a static pressure and voltage, the balloon may reach a state of equilibrium. The pressure is plotted as a function of the equilibrium stretch at several values of the voltage.

the liquid-like dielectric behavior, $D = \varepsilon E$, where E is the electric field.

Inserting Eqn (3) into Eqns (5) and (6), and eliminating D , we obtain that

$$\frac{d^2 \lambda}{dt^2} + g(\lambda, p, \Phi) = 0 \quad (7)$$

with

$$g(\lambda, p, \Phi) = 2\lambda - 2\lambda^{-5} - \frac{pR}{\mu H} \lambda^2 - 2 \frac{\varepsilon \Phi^2}{\mu H^2} \lambda^3 \quad (8)$$

where T is the dimensionless time ($T = t/R\sqrt{\rho/\mu}$). Equation (7) is the equation of motion that evolves the stretch of the balloon as a function of time, $\lambda(t)$. This equation is consistent with that derived in Mockensturm and Goulbourne.¹² In writing Eqns (7) and (8), we use the dimensionless pressure ($pR/\mu H$) and voltage ($\sqrt{\varepsilon/\mu} \Phi/H$).

BALLOON IN A STATE OF EQUILIBRIUM UNDER STATIC PRESSURE AND VOLTAGE

When the two loading parameters, p and Φ , are both static, the balloon may reach a state of equilibrium, of stretch λ_{eq} . In the state of equilibrium, the equation of motion, Eqn (7), reduces to

$$g(\lambda_{eq}, p, \Phi) = 0 \quad (9)$$

This nonlinear algebraic equation determines λ_{eq} for given values of p and Φ .

Figure 2 plots Eqn (9) as pressure–stretch curves at several values of voltage. When $\Phi = 0$, the problem reduces to that of a pressurized balloon, a well-known problem in the literature of nonlinear elasticity.²¹ As the balloon expands, the pressure first increases, reaches a peak and then decreases. The peak pressure corresponds to a critical state. When the applied pressure is above the peak, the balloon cannot reach a state of equilibrium. When the applied pressure is below the peak, corresponding to each value of the pressure are two values of the stretch. The value of the stretch on the rising part of the curve corresponds to a stable state of equilibrium, and the value of the stretch on the descending part of the curve corresponds to a state of unstable equilibrium.

When $\Phi \neq 0$, charges of opposite signs are induced on the two electrodes. The attraction between the electrodes causes the membrane of the balloon to reduce in thickness and increase in

Figure 3. Voltage is plotted as a function of the equilibrium stretch at several values of the pressure.

area. As shown in Fig. 2, the voltage lowers the critical pressure, and increases the stretch of any stable state of equilibrium.

Figure 3 plots the condition of equilibrium (9) as voltage–stretch curves at several values of pressure. When $p = 0$, as the balloon expands, the voltage first increases, reaches a peak and then decreases. This behavior is understood as follows.^{12,22–26} The voltage induces a positive charge on one electrode, and negative charge on the other electrode. The oppositely charged electrodes attract each other, so that the dielectric membrane reduces its thickness. For a prescribed voltage, the reduction in the thickness of the membrane increases the electric field. This positive feedback leads to electromechanical instability, or pull-in instability. The peak of the curve corresponds to the critical state. The critical voltage is reduced in the presence of the pressure.

SMALL-AMPLITUDE OSCILLATION AROUND A STATE OF EQUILIBRIUM

Consider a state of equilibrium, λ_{eq} . When the balloon is perturbed from this state of equilibrium, we write

$$\lambda(T) = \lambda_{\text{eq}} + \Delta(T) \quad (10)$$

where $\Delta(T)$ is the amplitude of perturbation, and is taken to be small. We then expand the function $g(\lambda, p, \Phi)$ as a power series in Δ around the equilibrium stretch λ_{eq} . Consequently, to the leading order in Δ , the equation of motion (Eqn (7)) becomes

$$\frac{d^2\Delta}{dT^2} + \Delta \frac{\partial g}{\partial \lambda}(\lambda_{\text{eq}}, p, \Phi) = 0 \quad (11)$$

where the partial derivative

$$\frac{\partial g(\lambda, p, \Phi)}{\partial \lambda} = 2 + 10\lambda^{-6} - 2\frac{pR}{\mu H}\lambda - 6\frac{\varepsilon\Phi^2}{\mu H^2}\lambda^2 \quad (12)$$

is evaluated at $\lambda = \lambda_{\text{eq}}$, and is a constant independent of time. We may call this partial derivative the stiffness of the balloon.

When the stiffness is negative, the perturbation $\Delta(T)$ will grow exponentially in time, and the state of equilibrium is unstable. When the stiffness is positive, the balloon will oscillate around the state of equilibrium, and the state of equilibrium is stable. Inspecting Eqn (11), we see that the natural frequency of the

Figure 4. Plotted on the plane of (p, Φ) are curves of constant natural frequency. The curve labeled by $\omega_0 = 0$ corresponds to the critical conditions. Above this curve, the balloon cannot reach a state of equilibrium. Below the curve, the balloon can reach a stable state of equilibrium. In this region, each point (p, Φ) corresponds to a state of stable equilibrium, and the balloon can oscillate around the state at the natural frequency ω_0 .

small-amplitude oscillation around the stable state of equilibrium is determined by

$$\tilde{\omega}_0^2 = \frac{\partial g}{\partial \lambda}(\lambda_{\text{eq}}, p, \Phi) \quad (13)$$

where $\tilde{\omega}_0 = \omega_0 R \sqrt{\rho/\mu}$ is the dimensionless natural frequency and ω_0 is the natural frequency.

When p and Φ are prescribed at static values, the equilibrium stretch λ_{eq} is determined by Eqn (9), and the dimensionless natural frequency $\tilde{\omega}_0$ is determined by Eqn (13). To avoid solving the nonlinear algebraic Eqn (9), we rearrange Eqns (9) and (13) to express p and Φ in terms of λ_{eq} and $\tilde{\omega}_0$, namely

$$\frac{\varepsilon\Phi^2}{\mu H^2} = -\lambda_{\text{eq}}^{-2} + 7\lambda_{\text{eq}}^{-8} - \frac{1}{2}\lambda_{\text{eq}}^{-2}\tilde{\omega}_0^2 \quad (14)$$

$$\frac{pR}{\mu H} = 4\lambda_{\text{eq}}^{-1} - 16\lambda_{\text{eq}}^{-7} + \lambda_{\text{eq}}^{-1}\tilde{\omega}_0^2 \quad (15)$$

Figure 4 plots the curves of constant natural frequency on the plane of (p, Φ) , using the following procedure. In Eqns (14) and (15), we fix ω_0 . For an arbitrary value of λ_{eq} , we obtain a point (p, Φ) . By varying λ_{eq} , we can plot the curve for a constant value of ω_0 . Each point on the curve labeled by $\omega_0 = 0$ corresponds to a critical state of the balloon. The coordinates of the point gives the critical values of p and Φ . When the pressure and voltage fall above this curve, the balloon cannot reach a state of equilibrium. When the pressure and voltage fall below the curve, the balloon can reach a stable state of equilibrium, and the natural frequency of the small-amplitude oscillation around the state of equilibrium can be read from the diagram. As indicated in Fig. 4, the frequency is normalized by a group of parameters, $R^{-1}\sqrt{\mu/\rho}$. These parameters are fixed for a given balloon. However, a change in the static pressure or the static voltage will tune the natural frequency.

PARAMETRIC EXCITATION

When the pressure or the voltage varies with time, the dynamic behavior of the balloon can be very complex. To illustrate the

complexity, we prescribe a static pressure p and a sinusoidal voltage:

$$\Phi(t) = \Phi_{dc} + \Phi_{ac} \sin(\Omega t) \quad (16)$$

where Φ_{dc} is the DC voltage, Φ_{ac} is the amplitude of the AC voltage, and Ω is the frequency of excitation. The equation of motion, Eqn (7), becomes

$$\frac{d^2\lambda}{dT^2} + 2\lambda - 2\lambda^{-5} - \frac{pR}{\mu H} \lambda^2 - 2 \frac{\varepsilon \Phi_{dc}^2}{\mu H^2} \left(1 + \frac{\Phi_{ac}}{\Phi_{dc}} \sin(\tilde{\Omega} t) \right)^2 \lambda^3 = 0 \quad (17)$$

where $\tilde{\Omega} = \Omega R \sqrt{\rho/\mu}$ is the dimensionless excitation frequency. The oscillatory voltage is a source of energy, and appears in a coefficient of the ordinary differential Eqn (17). Phenomena of this type are known as parametric excitation.^{15,16}

The time-dependent stretch $\lambda(T)$ can be obtained by solving Eqn (17) for any initial conditions. We set $pR/\mu H = 0.1$ and $\varepsilon \Phi_{dc}^2/\mu H^2 = 0.1$. Were these values of pressure and voltage static, the balloon could attain a state of equilibrium $\lambda_{eq} = 1.029$, or oscillate around the state of equilibrium at the natural frequency $\omega_0 R \sqrt{\rho/\mu} = 3.096$. We use this state of equilibrium as the initial conditions in our numerical simulations. We then apply the oscillatory voltage with specific values of Φ_{ac} and Ω . Once the numerical solution of $\lambda(T)$ attains a steady state of oscillation, we define the amplitude of oscillation as half of the difference between the maximal and minimal values of the stretch.

Figure 5 plots the amplitude of oscillation as a function of the frequency of excitation. The balloon resonates most strongly when the frequency of excitation is around the natural frequency, $\Omega \approx \omega_0$. The balloon also resonates when the frequency of excitation is several times the natural frequency, for example, $\Omega \approx 2\omega_0$, a response known as subharmonic resonance.¹⁶ In addition, the balloon resonates when the frequency of excitation is a fraction of the natural frequency, for example, $\Omega \approx \omega_0/2$, a response known as superharmonic resonance. Resonance at multiple values of the frequency of excitation is common for parametric excitation.^{27,28} As expected, the peak amplitudes at subharmonic, harmonic and superharmonic resonances increase with the AC voltage. The peak amplitudes of the fundamental frequency, as shown in Figs 5(b) and (c), are even unbounded when Φ_{ac}/Φ_{dc} increases to 0.3 and 0.5. The peak amplitudes also increase with the DC voltage and the pressure.

Figure 6 shows the numerical results of $\lambda(T)$ for three values of the frequency of excitation, $\Omega \approx \omega_0/2, \omega_0, 2\omega_0$. Independent of the frequency of excitation Ω , the balloon always oscillates near the natural frequency ω_0 , as defined by the small-amplitude oscillation around a state of equilibrium. Figure 6 shows a phase shift between the voltage input and the stretch output. Such a phase shift is often found in damped and undamped nonlinear oscillators; for example, the undamped Duffing oscillator is discussed in Jordan and Smith.¹⁵ In general, not only the viscous effect, but also the nonlinearity can lead to a phase shift between the excitation and the oscillation.

Experimental data reported in the literature show that the frequency of the oscillation is double, or is close to, that of the AC voltage.^{10,11} For example, in Fig. 70 of Fox,¹¹ $\Omega \approx \omega_0/2$, while in Fig. 72 of Fox,¹¹ $\Omega \approx \omega_0$. Our numerical results not only show superharmonic and harmonic resonance, but also show subharmonic resonance with $\Omega \approx 2\omega_0$. This discrepancy between theory and experiment needs to be resolved in future studies.

Figure 5. Excited by a sinusoidal voltage, the balloon resonates at several values of the frequency of excitation Ω . The oscillating amplitude of the balloon is plotted as a function of the frequency of excitation for $pR/\mu H = 0.1$ and $\varepsilon \Phi_{dc}^2/\mu H^2 = 0.1$, at selected values of Φ_{ac}/Φ_{dc} .

JUMP IN OSCILLATING AMPLITUDE WHEN THE FREQUENCY OF EXCITATION VARIES

To obtain other essential characteristics of the nonlinear oscillation, we study Eqn (17) using the method of harmonic balance.^{15,16} The time-dependent stretch is approximated as

$$\lambda(T) = \lambda_{eq} + a(T) \cos \omega T + b(T) \sin \omega T \quad (18)$$

where λ_{eq} is the stretch in the state of equilibrium, a and b are time-dependent amplitudes and ω is the dimensionless frequency of oscillation. We assume that the amplitudes vary slowly with time. We use the truncated Fourier series, and neglect terms of high frequencies, $2\omega, 3\omega$, etc.

We are interested in the harmonic oscillation in a steady state, where a and b are constants, and the balloon oscillates at a frequency equal to the frequency of excitation, $\omega = \tilde{\Omega}$. With the method of harmonic balance, we substitute Eqn (18) into Eqn (17), set the coefficients of the constant $\cos \tilde{\Omega} T$ and $\sin \tilde{\Omega} T$ to be zero, and neglect terms of higher frequencies. Then we obtain three nonlinear equations for λ_{eq} , a and b . We solve these nonlinear equations for a and b using the Newton–Raphson method. Figure 7 plots the oscillating amplitude of the balloon,

Figure 6. Superharmonic, harmonic and subharmonic responses ($pR/\mu H = 0.1$, $\varepsilon \Phi_{dc}^2/\mu H^2 = 0.1$ and $\Phi_{ac}/\Phi_{dc} = 0.1$).

$\sqrt{a^2 + b^2}$, as a function of the frequency of excitation $\tilde{\Omega}$. Upon increasing the frequency of excitation, the steady-state solution will start from point O, to A, to D, then jump to point E, then to F, and to O'. However, upon decreasing the frequency of excitation, the steady state will start from point O', to F, to E and C. Similar phenomena of hysteresis have been reported in many parametrically excited oscillators.^{16,29}

The above interpretations are better understood when we study how the amplitudes vary with time, $a(T)$ and $b(T)$. Since a and b are taken to vary with time slowly, d^2a/dT^2 and d^2b/dT^2 are neglected. Taking second derivative of Eqn (18) with respect to T , we obtain that

$$\frac{d^2\lambda}{dT^2} = \left(-\omega^2 a + 2\omega \frac{db}{dT}\right) \cos \omega T + \left(-2\omega \frac{da}{dT} - \omega^2 b\right) \sin \omega T \quad (19)$$

Substituting Eqn (19) into Eqn (17), setting $\tilde{\Omega} = \omega$ and equating the coefficients of $\cos(\tilde{\Omega}T)$ and $\sin(\tilde{\Omega}T)$ to zero, we obtain that

$$\frac{da}{dT} = F(a, b); \quad \frac{db}{dT} = G(a, b) \quad (20)$$

The two functions $F(a, b)$ and $G(a, b)$ are lengthy and are not listed here. Given initial values $a(0)$ and $b(0)$, we can evolve Eqn (20) to obtain $a(T)$ and $b(T)$.

Figure 7. Steady-state solutions when $pR/\mu H = 0.1$, $\varepsilon \Phi_{dc}^2/\mu H^2 = 0.1$ and $\Phi_{ac}/\Phi_{dc} = 0.1$.

Figure 8. Phase plane of a and b when $\Omega R\sqrt{\rho/\mu} = 2.4$, $pR/\mu H = 0.1$, $\varepsilon \Phi_{dc}^2/\mu H^2 = 0.1$ and $\Phi_{ac}/\Phi_{dc} = 0.1$.

Figure 8 shows the phase plane of (a, b) . Steady-state solution 1, related to point A in Fig. 7, is a center point. Steady-state solution 2, related to point B in Fig. 7, is a saddle point. Steady-state solution 3, related to point C in Fig. 7, is a center point. Figure 8 shows that the parametric response depends on the initial condition. For example, if the initial condition is close to the center point 1, $a(0) = 0$ and $b(0) = 0.1$, the final path will cycle around this center point. If the initial condition is close to the saddle point 2, however, the final path will not stay near the saddle point, but will follow either a larger cycle, say path (1), or a small cycle, say path (2).

The stability analysis of steady-state solution is as follows. With the infinitesimal perturbation for the steady-state solution, let

$$a(T) = a^0 + \alpha(T); \quad b(T) = b^0 + \beta(T) \quad (21)$$

where a^0 and b^0 are the steady-state solution and $\alpha(T)$ and $\beta(T)$ are infinitesimal perturbation. Substituting Eqn (21) into Eqn (20), keeping the linear term for α and β , we obtain

$$\begin{bmatrix} \frac{d\alpha}{dT} \\ \frac{d\beta}{dT} \end{bmatrix} = \begin{bmatrix} \frac{\partial F}{\partial a} & \frac{\partial F}{\partial b} \\ \frac{\partial G}{\partial a} & \frac{\partial G}{\partial b} \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} \quad (22)$$

The partial derivatives of the functions $F(a, b)$ and $G(a, b)$ are evaluated at the steady-state solution (a^0, b^0) . The steady-state solution is stable when the eigenvalues of the matrix in Eqn (22) have negative real parts. This analysis produces results indicated on the phase plane.

CONCLUDING REMARKS

We describe a dielectric elastomer balloon with an equation of motion of one degree of freedom. When the pressure and the voltage are static, the balloon may reach a state of equilibrium. We study the stability of the state of equilibrium against small perturbation, and calculate the natural frequency of the small-amplitude oscillation around the state of equilibrium. The natural frequency is tunable by varying the pressure or the voltage. When the pressure is static but the voltage is sinusoidal, the balloon resonates at multiple values of the frequency of excitation, giving rise to superharmonic, harmonic and subharmonic responses. Furthermore, when the frequency of excitation is changed continuously, the oscillating amplitude of the balloon may jump at certain values of the frequency of excitation, exhibiting hysteresis. We hope to further analyze the nonlinear dynamic behavior by using models of many degrees of freedom, including dissipation due to viscosity and leakage. We also hope that future experiments will confirm the theoretical predictions.
